

Math refresher B: Fundamentals of probability

Lecture 2

Tunga Kantarcı, Fall 2025

Fundamentals of probability: Random variables and their probability distributions: Random variable

A **random variable** is a numerical quantity whose value is uncertain before an experiment, but becomes fixed once the outcome of the experiment is revealed.

Fundamentals of probability: Random variables and their probability distributions: Random variable: Example

Consider flipping a fair coin 10 times as an experiment. The number of times the coin lands on heads is a **random variable**. This number is random because it is the **probabilistic outcome of each flip**. Before flipping the coin, the experiment, we know that the **possible** values range from 0 to 10, but the actual number of heads is uncertain.

Once we perform the 10 flips and count the number of heads, we obtain a specific **realization** of the random variable for that trial. From another trial, we could get a different realization.

Fundamentals of probability: Random variables and their probability distributions: Random variable: Notation

We indicate collections of **random variables** using an uppercase letter and subscripts to distinguish individual elements within the group:

$$\{X_i : i = 1, \dots, n\}$$

n is the **sample size**, representing the number of observations or trials.

Fundamentals of probability: Random variables and their probability distributions: Random variable: Notation

Before the experiment, each X_i is a random variable that can take on values from a set of **possible outcomes**, typically denoted in lowercase:

$$\{x_i : i = 1, \dots, k\}$$

k is the number of distinct possible outcomes that **any single** X_i might take.

After the experiment or sampling process is complete, we observe specific numerical values for each X_i . These are called **realizations**, and we denote them using lowercase letters with matching subscripts:

$$\{x_i : i = 1, \dots, n\}$$

Fundamentals of probability: Random variables and their probability distributions: Random variable: Notation

Following Wooldridge's convention, we use lowercase x_i both for possible outcomes and observed values. The distinction is made through context: before sampling, x_i refers to a generic possible value that X_i might take, from among k possibilities; after sampling, it denotes the realized value of X_i in a sample of size n .

Fundamentals of probability: Random variables and their probability distributions: Random variable: Notation: Example

Suppose we record last year's income for $n = 20$ randomly selected households. We represent these income values as **random variables**:

$$X_1, X_2, \dots, X_{20}$$

Each X_i reflects the income of the i -th household and is subject to randomness due to the sampling process.

Fundamentals of probability: Random variables and their probability distributions: Random variable: Notation: Example

Before data collection, these variables are not associated with specific values, they represent the underlying probabilistic structure. Each X_i can take on values from a set of **possible outcomes**, which in this context is the set of non-negative real numbers.

Once the data is collected, we observe specific numerical values, the **realizations** of these random variables:

$$x_1, x_2, \dots, x_{20}$$

These realizations form the actual dataset used for analysis. While the X_i capture uncertainty before observation, the x_i are fixed values obtained from the sample.

Fundamentals of probability: Random variables and their probability distributions: Discrete random variable

A **discrete random variable** is one that takes on only a finite number of values.

Fundamentals of probability: Random variables and their probability distributions: Discrete random variable

To fully describe the **behavior** of a random variable, we only need the **probability** that it takes on values.

Fundamentals of probability: Random variables and their probability distributions: Discrete random variable: Example

A **Bernoulli random variable** is the simplest example of a **discrete random variable**. It can take on only the values 0 and 1. It is conventional to refer to the event $X = 0$ as a “failure” and the event $X = 1$ as a “success”.

Fundamentals of probability: Random variables and their probability distributions: Discrete random variable: Example

To fully describe the **behavior** of a Bernoulli **variable**, we only need the **probability** that it takes on the value 1. In the coin-flipping example, if the coin is “fair,” then

$$P(X = 1) = \frac{1}{2}$$

which reads as “the probability that X equals one is one-half”. Since probabilities must sum to one, it follows that

$$P(X = 0) = \frac{1}{2}$$

as well.

Fundamentals of probability: Random variables and their probability distributions: Discrete random variable

More generally, any discrete random variable is completely described by listing

- its possible values, and
- the associated probability that it takes on each value.

If X takes on the k possible values $\{x_1, x_2, \dots, x_k\}$, then the probabilities p_1, p_2, \dots, p_k are defined by

$$p_j := P(X = x_j), \quad j = 1, 2, \dots, k$$

where each p_j is between 0 and 1, and

$$p_1 + p_2 + \dots + p_k = 1.$$

This is read as: “The probability that X takes on the value x_j is equal to p_j ”. We summarize this information as follows.

Fundamentals of probability: Random variables and their probability distributions: Discrete random variable: PMF

The **probability mass function**, PMF, of X , summarizes the information concerning the possible outcomes of X and the corresponding probabilities:

$$f_X(X = x_j) = p_j$$

for $j = 1, 2, \dots, k$.

Fundamentals of probability: Random variables and their probability distributions: Discrete random variable: PMF: Notation

We typically use the shorthand:

$$f_X(x)$$

This denotes the value of the PMF of the random variable X , evaluated at the point x . In other words, the probability that the random variable X takes on the particular value x .

Sometimes even the subscript X is omitted, and we simply write

$$f(x)$$

when the context makes clear which random variable is considered.

Fundamentals of probability: Random variables and their probability distributions: Discrete random variable: PMF

Given the PMF of any discrete random variable, it is simple to compute the probability of any event involving that random variable.

Fundamentals of probability: Random variables and their probability distributions: Discrete random variable: PMF: Example

In basketball, a free throw is when a player gets to shoot the ball from a special line without anyone trying to block them. If the ball goes in the hoop, they score one point. Suppose a player gets two chances to shoot. Let X be the number of successful free throws. Then X can be:

- $X = 0$: The player missed both shots
- $X = 1$: The player made one successful shot
- $X = 2$: Both shots are successful

So, X can take on three values: $\{0, 1, 2\}$ depending on how many free throws the player makes.

Fundamentals of probability: Random variables and their probability distributions: Discrete random variable: PMF: Example

Assume that the PMF of X is given by:

- $f(0) = 0.20$
- $f(1) = 0.44$
- $f(2) = 0.36$

The three probabilities sum to one, as they must. Using this PMF, we can calculate the probability that the player makes at least one free throw:

$$P(X \geq 1) = P(X = 1) + P(X = 2) = 0.44 + 0.36 = 0.80.$$

Fundamentals of probability: Random variables and their probability distributions: Discrete random variable: PMF: Example

The PMF of the number of free throws made out of two attempts.

Fundamentals of probability: Random variables and their probability distributions: Continuous random variable

A **continuous random variable** can take any value. Although real-world measurements are recorded in discrete units, variables with a wide range of values are often modeled as continuous for simplicity.

Fundamentals of probability: Random variables and their probability distributions: Continuous random variable: Example

The **price** of a product might be **measured in cents**, which is technically discrete. However, since prices can vary by fractions of a cent and **span a large range**, it is more practical to treat price as a continuous variable.

Fundamentals of probability: Random variables and their probability distributions: Continuous random variable: PDF

A **probability density function**, PDF, describes the likelihood of outcomes for a continuous random variable. We denote a PDF with

$$f_X(x)$$

This reads as: the value of the PDF of the random variable X , evaluated at the point x .

Fundamentals of probability: Random variables and their probability distributions: Continuous random variable: PDF

A continuous random variable can take on infinitely many possible values. Therefore the probability of it taking on any exact value is 0. This is not a limitation, it is a property of continuous distributions.

Fundamentals of probability: Random variables and their probability distributions: Continuous random variable: PDF

The value of the PDF at a point x , denoted

$$f(x)$$

does **not** represent the probability that $X = x$, since that probability is 0. Instead, it reflects the relative likelihood of values near x compared to other regions of the distribution. If, say, $f(x_1) > f(x_2)$, then values near x_1 are more likely to occur than values near x_2 .

Fundamentals of probability: Random variables and their probability distributions: Continuous random variable: PDF

To find actual probabilities, we **use the PDF over intervals**. That is, for constants a and b , the probability that X lies between them is given by the area under the PDF between those points:

$$P(a \leq X \leq b) = \int_a^b f(x) dx$$

The total area under the PDF is always equal to 1.

Fundamentals of probability: Random variables and their probability distributions: Continuous random variable: PDF: Example

The PDF of the t -distribution is given by

$$f_T(t) = \frac{\Gamma\left(\frac{\nu+1}{2}\right)}{\sqrt{\nu\pi} \Gamma\left(\frac{\nu}{2}\right)} \left(1 + \frac{t^2}{\nu}\right)^{-\frac{\nu+1}{2}}$$

where

- t is the variable
- ν is the degrees of freedom, and determines the shape of the PDF, and
- $\Gamma(\cdot)$ denotes the gamma function.

Fundamentals of probability: Random variables and their probability distributions: Continuous random variable: PDF: Example

The gamma function $\Gamma(x)$ is a continuous extension of the factorial, defined for $x > 0$ by:

$$\Gamma(x) = \int_0^{\infty} t^{x-1} e^{-t} dt$$

It satisfies $\Gamma(n) = (n-1)!$ for any positive integer n .

Fundamentals of probability: Random variables and their probability distributions: Continuous random variable: PDF: Example

Consider

$$P(-1.9623 \leq T \leq 1.9623) = \int_{-1.9623}^{1.9623} f_T(t) dt \approx 0.9409$$

Let's plot it for $\nu = 999$.

Fundamentals of probability: Random variables and their probability distributions: Continuous random variable: PDF: Example

Fundamentals of probability: Conditional distributions, joint distributions, and independence: Conditional distribution

The **conditional probability** of event y given event x is defined as:

$$P(y | x) = \frac{P(x, y)}{P(x)}$$

This represents the probability that event y occurs, assuming that event x has occurred. Here the

- denominator restricts our attention to the cases where x happens, and within those cases
- numerator represents the probability that both events x and y happen together, and

So we are asking: **out of all the times x occurs, how often does y also occur?**

Fundamentals of probability: Conditional distributions, joint distributions, and independence: Conditional distribution

In econometrics, we are often interested in understanding the relationship between two random variables, X and Y . One way to describe this relationship is through the conditional distribution of Y given X . This distribution tells us how the probabilities associated with Y vary depending on the value of X . For discrete random variables, this is captured by the conditional PMF:

$$f_{Y|X}(y | x) = \frac{f_{X,Y}(x, y)}{f_X(x)}$$

This is interpreted as the probability that $Y = y$, given that $X = x$. It reflects statistical association, not necessarily causation.

Fundamentals of probability: Conditional distributions, joint distributions, and independence: Conditional distribution

What is the intuition?

$$f_{Y|X}(y | x)$$

By fixing X at a specific value x , we examine how the distribution of Y behaves under that condition. By comparing these conditional distributions across different values of x , we begin to understand how the distribution of Y varies with X .

Fundamentals of probability: Conditional distributions, joint distributions, and independence: Joint distribution

Let X and Y be discrete random variables. The pair (X, Y) has a **joint distribution**, which is fully characterized by its joint PMF:

$$f_{X,Y}(x, y) = P(X = x, Y = y) = P(Y = y \mid X = x) \cdot P(X = x)$$

Fundamentals of probability: Conditional distributions, joint distributions, and independence: Independence

Random variables X and Y are said to be **independent** if and only if

$$\begin{aligned}P(X = x, Y = y) &= P(X = x) \cdot P(Y = y \mid X = x) \\&= P(X = x) \cdot P(Y = y)\end{aligned}$$

Independence means that the **probability of one variable's outcome does not change depending on the value of the other**. When this holds, the probability that $X = x$ and $Y = y$ occur together is simply the product of their individual probabilities: These individual probabilities are called marginal PMFs.

Fundamentals of probability: Conditional distributions, joint distributions, and independence: Independence

“if and only if”, for the second term of the product above, means:

- If conditional PMF = marginal PMF, then independence
- If independent, then conditional PMF = marginal PMF

So it is a perfect two-way relationship.

Fundamentals of probability: Features of probability distributions: Measure of central tendency: Expected value

Let

- X be a discrete random variable taking on a finite set of possible outcomes $\{x_1, x_2, \dots, x_k\}$, and
- $f(x)$ represent the PMF of X

The expected value of X is given by

$$E(X) = x_1 f(x_1) + x_2 f(x_2) + \dots + x_k f(x_k) = \sum_{i=1}^k x_i f(x_i)$$

This expression represents a weighted average of all possible values that X can take, where the weights are given by the corresponding probabilities. It reflects the average value we expect to see, our belief.

Fundamentals of probability: Features of probability distributions: Measure of central tendency: Expected value

The expected value is the theoretical average of all possible outcomes of a random variable. For this reason, it is often referred to as the **population mean**, where X denotes a variable defined over an entire population.

The **sample mean**, on the other hand, is an estimate of the expected value calculated from observed data.

Fundamentals of probability: Features of probability distributions: Measure of central tendency: Expected value: Example

Suppose that X takes on the values $-1, 0, 2$, with probabilities $\frac{1}{8}, \frac{1}{2}, \frac{3}{8}$, respectively. Then the **population mean** is,

$$E(X) = -1 \cdot \frac{1}{8} + 0 \cdot \frac{1}{2} + 2 \cdot \frac{3}{8} = \frac{5}{8}$$

Fundamentals of probability: Features of probability distributions: Measure of central tendency: Expected value: Example

Now suppose we draw a random sample of 8 observations from this distribution: $\{-1, 0, 0, 0, 0, 2, 2, 2\}$. Notice that -1 occurs 1 out of 8 times, 0 occurs 4 out of 8 times, and 2 occurs 3 out of 8 times. These observed frequencies happen to match the theoretical probabilities: $\frac{1}{8}$, $\frac{1}{2}$, and $\frac{3}{8}$, respectively. The **sample mean** is:

$$\bar{x} = \frac{-1 + 0 + 0 + 0 + 0 + 2 + 2 + 2}{8} = \frac{5}{8}$$

This is a purely arithmetic calculation, no probability is involved. It just averages the observed values. In this case, the sample mean \bar{x} happens to equal the expected value $E(X)$, because the sample proportions match the theoretical probabilities. This does not have to be the case.

Fundamentals of probability: Features of probability distributions: Measure of central tendency: Expected value: Properties

exp. val. property 1: For any constant c :

$$E(c) = c$$

This shows that if a random variable always takes the same value c , then its average over all outcomes is simply c itself.

Fundamentals of probability: Features of probability distributions: Measure of central tendency: Expected value: Properties

exp. val. property 2: For any constants a and b :

$$E(aX + b) = aE(X) + b$$

This shows that expectation is a linear operator: scaling a random variable scales its expected value, and shifting it adds the same constant to the expectation.

Fundamentals of probability: Features of probability distributions: Measure of variability: Variance

For a random variable X , let $M := E(X)$.

There are various ways to **measure how far X is from its expected value**, but the simplest one to work with is the squared difference

$$(X - M)^2$$

The squaring eliminates the sign from the distance measure; the resulting positive value corresponds to our intuitive notion of distance, and treats values above and below M symmetrically.

Fundamentals of probability: Features of probability distributions: Measure of variability: Variance

Since X can take on different values depending on the outcome, the squared difference $(X - M)^2$ is itself a random variable. To **summarize this variability** with a single number, just as we use the population mean to summarize central tendency, take the **population average of these squared differences** across all possible outcomes. This gives a measure of how much X **typically** deviates from its mean:

$$\text{Var}(X) = E[(X - M)^2]$$

Variance is often denoted σ_X^2 , or simply σ^2 , when the context is clear.

Fundamentals of probability: Features of probability distributions: Measure of variability: Variance

Random variables with the same mean but different distributions.

Fundamentals of probability: Features of probability distributions: Measure of variability: Variance: Properties

var. property 1: The variance of any constant is 0.

Fundamentals of probability: Features of probability distributions: Measure of variability: Variance: Properties

var. property 2: For constants a and b ,

$$\text{Var}(aX + b) = a^2 \text{Var}(X)$$

This means that adding a constant to a random variable does not change the variance, but multiplying a random variable by a constant scales the variance by the square of that constant. For example, if X denotes temperature in Celsius and $Y = 32 + \frac{9}{5}X$ is temperature in Fahrenheit, then

$$\text{Var}(Y) = \left(\frac{9}{5}\right)^2 \text{Var}(X)$$

Fundamentals of probability: Features of probability distributions: Measure of variability: Variance: Properties

var. property 3: For constants a and b ,

$$\text{Var}(aX + bY) = a^2\text{Var}(X) + b^2\text{Var}(Y) + 2ab\text{Cov}(X, Y)$$

We are yet to learn about covariance.

Fundamentals of probability: Features of probability distributions: Measure of variability: Standard deviation

Standard deviation of a random variable is simply the square root of the variance:

$$\text{sd}(X) = \sqrt{\text{Var}(X)}$$

The standard deviation is often denoted σ_X , or simply σ when this is clear from the context.

Fundamentals of probability: Features of joint and conditional distributions: Measures of association

The probability distribution of a random variable X is

$$f_X(x)$$

and it describes all the information about its behavior.

The expected value and variance of X are **single numbers** that **summarize** this entire distribution.

Fundamentals of probability: Features of joint and conditional distributions: Measures of association

The joint PDF of two random variables is

$$f_{X,Y}(x,y)$$

and it completely describes the **relationship** between them.

We also need a **single number** to **summarize** this joint distribution. That is, it is useful to have a **summary measure** of **how two random variables vary with one another**, on average.

Fundamentals of probability: Features of joint and conditional distributions: Measures of association

Fundamentals of probability: Features of joint and conditional distributions: Measures of association: Covariance

Let $M_X := E(X)$ and $M_Y := E(Y)$, and consider the random variable

$$(X - M_X)(Y - M_Y)$$

If

- $X > M_X$ and $Y > M_Y$, or
- $X < M_X$ and $Y < M_Y$,

then the product is positive. On the other hand, if

- $X > M_X$ and $Y < M_Y$, or
- vice versa,

then the product is negative. Can this product tell us anything about the relationship between X and Y ?

Fundamentals of probability: Features of joint and conditional distributions: Measures of association: Covariance

Covariance between two random variables X and Y is defined as:

$$\text{Cov}(X, Y) = E[(X - M_X)(Y - M_Y)]$$

It says, if

- positive, then, on **on average**, when X is above its mean, Y is also above its mean
- negative, then, on average, when X is above its mean, Y is below its mean

Covariance measures the amount of linear dependence between two random variables. If positive, two random variables move in the same direction. If negative, they move in opposite directions. It is often denoted σ_{XY} .

Fundamentals of probability: Features of joint and conditional distributions: Measures of association: Covariance: Properties

Because covariance is a measure of how two random variables are related, it is natural to ask how covariance is related to the notion of independence:

cov. property 1: If X and Y are independent, then

$$\text{Cov}(X, Y) = 0$$

Fundamentals of probability: Features of joint and conditional distributions: Measures of association: Covariance: Properties

It is important to note that if the covariance between two random variables X and Y is zero, that is,

$$\text{Cov}(X, Y) = 0,$$

this does not necessarily imply that X and Y are independent. 0 covariance only indicates that there is **no linear** relationship between the variables. They may still be dependent in a nonlinear way.

Fundamentals of probability: Features of joint and conditional distributions: Measures of association: Covariance: Properties

cov. property 2: For any constants a and b ,

$$\text{Cov}(aX, bY) = ab\text{Cov}(X, Y)$$

An important implication of this property is that the covariance between two random variables is sensitive to the units of measurement. That is, multiplying one or both variables by a constant, such as converting dollars to euros, will scale the covariance accordingly. This matters in economics because variables like prices, wages, and inflation rates can be expressed in different units without changing their underlying relationships, yet the numerical value of their covariance will change depending on those units. This is a deficiency and it is overcome by the [correlation coefficient](#).

Fundamentals of probability: Features of joint and conditional distributions: Measures of association: Correlation coefficient

The **correlation coefficient** between X and Y is given by

$$\text{Corr}(X, Y) = \frac{\text{Cov}(X, Y)}{\text{sd}(X) \cdot \text{sd}(Y)} = \frac{\text{Cov}(X, Y)}{\sigma_X \sigma_Y}$$

Because σ_X and σ_Y are positive, $\text{Cov}(X, Y)$ and $\text{Corr}(X, Y)$ always have the same sign, and

$$\text{Corr}(X, Y) = 0 \quad \text{if and only if} \quad \text{Cov}(X, Y) = 0.$$

The corr. coef. is sometimes denoted ρ_{XY} .

Fundamentals of probability: Features of joint and conditional distributions: Measures of association: Correlation coefficient: Properties

corr. coef. property 1: $-1 \leq \text{Corr}(X, Y) \leq 1$

If

- $\rho_{XY} = 0$, there is no linear relationship between X and Y , and X and Y are said to be uncorrelated random variables
- ρ_{XY} is close to 1 or -1 , the linear relationship is stronger

This shows that correlation between X and Y is invariant to the units of measurement of either X or Y . This is stated more generally in the second property.

Fundamentals of probability: Features of joint and conditional distributions: Measures of association: Correlation coefficient: Properties

corr. coef. property 2: For any constants a and b ,

$$\text{Corr}(aX, bY) \stackrel{!}{=} \text{Corr}(X, Y)$$

If $ab < 0$, then

$$\text{Corr}(aX, bY) = -\text{Corr}(X, Y)$$

This says that multiplying one or both variables by a constant, such as converting dollars to euros, does not scale the correlation coefficient accordingly.

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation

Covariance and correlation measure the linear relationship between two random variables, **without implying that one depends on the other**.

In social sciences, we often seek to model how one variable, denoted Y , varies with another variable, say X . Moreover, if the relationship between Y and X is nonlinear, we aim to characterize that as well. We refer to Y as the “dependent variable”, and X as the “independent variable”, though these terms reflect modeling convention and not necessarily causal inference.

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation

We already introduced the notion of conditional PDF of Y given $X = x$:

$$f(y \mid x)$$

Thus, we might want to see how the distribution of y , say wages, changes with x , say education level.

However, we usually want to have a simple way of summarizing this distribution. A single number will no longer suffice, because the distribution of Y given $X = x$ generally depends on the value of x .

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation

We can summarize the relationship between Y and X by looking at the conditional expectation of Y given X , sometimes called the **conditional mean**. The idea is this: suppose we know that X has taken on a particular value, say, x . Then, we can compute the expected value of Y , at the known x . We denote this expected value by

$$E(Y \mid X = x)$$

Generally, as x changes, so does $E(Y \mid x)$. We always use $E(Y \mid x)$ as shorthand.

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation

If Y is a discrete random variable taking on possible outcomes $\{y_1, y_2, \dots, y_n\}$, then

$$E(Y \mid X = x) = \sum_{i=1}^n y_i \cdot f(y_i \mid x)$$

- LHS tells: fix X at a specific value x , and consider the mean of the PMF of Y at that x . This will give the expected value of Y at that x .
- RHS tells: a weighted average of the possible outcomes y_i , where the weights are the conditional probabilities $f(y_i \mid x)$.

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Example

Let (X, Y) represent the population of all working individuals, where X is years of education and Y is hourly wage. Then,

$$E(Y \mid X = 12)$$

is the average hourly wage for all people in the population with 12 years of education, roughly a high school education. Similarly,

$$E(Y \mid X = 16)$$

is the average hourly wage for all people with 16 years of education. Tracing out the expected value for various levels of education provides important information on how wages and education are related. The following plot for an illustration.

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Example

The expected value of hourly wage given various levels of education.

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Example

In econometrics, we specify simple functions to summarize this relationship.

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Example

Suppose that the expected value of $WAGE$ given $EDUC$ is the linear function:

$$E(WAGE \mid EDUC) = 1.05 + 0.45 \cdot EDUC$$

If this relationship holds in the population of working people, the average wage for people with 8 years of education is:

$$1.05 + 0.45 \cdot 8 = \$4.65$$

The coefficient on education implies that each year of education increases the expected hourly wage by \$0.45, or 45 cents.

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Example

Conditional expectations can also be nonlinear functions. For example, suppose that:

$$E(Y | x) = \frac{10}{x}$$

where X is a positive random variable. This could represent a demand function, where Y is quantity demanded and X is price. If Y and X are related in this way, an analysis of linear association, such as correlation analysis, would be inadequate. Let's plot this function.

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Example

Graph of $E(Y|x) = 10/x$.

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Properties

con. exp. property 1: For any function $c(X)$,

$$E[c(X) \mid X] = c(X)$$

This means that functions of X behave as constants when we compute expectations conditional on X . For example, $E[X^2 \mid X] = X^2$. Intuitively, this simply means that if we know X , then we also know X^2 .

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Properties

con. exp. property 2: For functions $a(X)$ and $b(X)$,

$$E[a(X)Y + b(X) \mid X] = a(X) \cdot E(Y \mid X) + b(X)$$

For the first term of the summation: Given X , $a(X)$ is treated as a constant, so expected value property 2 applies.

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Properties: Example

We can compute the conditional expectation of $XY + 28$ as

$$E[XY + 28 \mid X] = X \cdot E(Y \mid X) + 28$$

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Properties

con. exp. property 3: If X and Y are independent, then

$$E(Y | X) = E(Y)$$

This property means that, if X and Y are independent, then the expected value of Y given X does not depend on X . In this case, $E(Y | X)$ always equals the (unconditional) expected value of Y .

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Properties: Example

In the wage and education example, if wages were independent of education, then the average wages of high school and college graduates would be the same:

$$E(WAGE \mid EDUC) = E(WAGE)$$

Because this is almost certainly false, we cannot assume that wage and education are independent.

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Properties

con. exp. property 4: The law of iterated expectations says

$$E(E(Y | X)) = E(Y)$$

This says that take the mean of Y within each X , then average those means across X . This reproduces the overall mean of Y .

Fundamentals of probability: Features of joint and conditional distributions: Conditional expectation: Properties: Example

Imagine a school with two classrooms. Classroom A has 20 students with average height 150 cm, and Classroom B has 30 students with average height 170 cm. First compute the average height within each classroom. Then take a weighted average of these means, weighting by classroom size:

$$\frac{20}{50} \cdot 150 + \frac{30}{50} \cdot 170 = 162.$$

This equals the overall average height of all 50 students:

$$\frac{20 \cdot 150 + 30 \cdot 170}{50} = 162,$$

showing that averaging in two steps reproduces the direct average.

Fundamentals of probability: Features of joint and conditional distributions: Conditional variance

Given random variables X and Y , the variance of Y , conditional on $X = x$, is simply the variance associated with the conditional distribution of Y given $X = x$:

$$\text{Var}(Y \mid X = x) = E[(Y - E(Y \mid x))^2 \mid x]$$

This is simply the variance of Y , except that the deviation is taken from the conditional mean $E(Y \mid x)$ rather than the unconditional mean $E(Y)$.

Fundamentals of probability: Features of joint and conditional distributions: Conditional variance: Example

Let $Y = INCOME$ and $X = EDUCATION$, both measured annually for the population of all families. Suppose that

$$\text{Var}(INCOME \mid EDUCATION) = 400 + 0.25 \cdot EDUCATION$$

This expression suggests that as education increases, the variance in income also rises. One possible explanation is that individuals with higher education levels have access to a broader range of occupations, which offer more diverse wage structures. It is important to recognize that the relationship between the variance of savings and income is entirely separate from the relationship between the expected value of savings and income.

Fundamentals of probability: Features of joint and conditional distributions: Conditional variance: Properties

cond. cov. property 1: If X and Y are independent, then

$$\text{Var}(Y | X) = \text{Var}(Y)$$

This property is straightforward: when X and Y are independent, the distribution of Y given X does not depend on X .

Fundamentals of probability: Probability distributions: t distribution

The t -distribution is a workhorse in statistical inference, especially in regression analysis. Let

- Z have a standard normal distribution,
- X have a chi-square distribution with ν degrees of freedom, and
- Z and X be independent.

Then, the random variable

$$T = \frac{Z}{\sqrt{X/\nu}}$$

has a t -distribution with ν degrees of freedom. We denote this by $T \sim t_\nu$.

Fundamentals of probability: Probability distributions: t distribution

We have seen earlier in this lecture that the PDF of the t -distribution is given by:

$$f_T(t) = \frac{\Gamma\left(\frac{\nu+1}{2}\right)}{\sqrt{\nu\pi} \Gamma\left(\frac{\nu}{2}\right)} \left(1 + \frac{t^2}{\nu}\right)^{-\frac{\nu+1}{2}}$$

Fundamentals of probability: Probability distributions: t distribution

Using computer simulation, let's sample 1,000 values from the t-distribution and visualize their distribution.

Fundamentals of probability: Probability distributions: t distribution

Fundamentals of probability: Probability distributions: t distribution

By sampling more values, say 1,000,000, from the t distribution and plotting them, we can approximate its shape.

Fundamentals of probability: Probability distributions: t distribution

Fundamentals of probability: Probability distributions: t distribution

Evaluating the PDF at many values of t yields a smooth curve that represents the t distribution.

Fundamentals of probability: Probability distributions: t distribution

Fundamentals of probability: Probability distributions: t distribution

Let's visualize the t-distribution across different degrees of freedom.
